

How to Read Prediction (Updated)

How to interpret it (simple mental model)

- Your risk (37.76%) = the model's estimate for you.
- Baseline risk (62.59%) = the model's starting point for a typical person in the data it learned from (not you).
- 62.59% is the model's average predicted risk across the dataset it was trained on.
- The two lists explain what moved you away from that starting point:
 - What increased your risk = things pushing your score up
 - What decreased your risk = things pushing your score down

What judgments they can safely make

- 1 Look at the biggest positive items (largest +% points). These are the strongest reasons the model thinks your risk is higher.
- 2 Focus on modifiable factors (LDL, BP, alcohol, sugar, BMI, activity, sleep).
- 3 The biggest negative items (largest –% points) show what is helping reduce your risk (e.g., not smoking, good HDL).
- 4 Bigger absolute % points = stronger influence on this prediction.

What they should NOT conclude

- 1 Baseline is not your personal default risk.
- 2 These contributions are not proof of causation.
- 3 This is not a medical diagnosis, but decision support.

One-line takeaway

My estimated risk is 37.76%. The model suggests my risk is increased by LDL, alcohol, and gender, and reduced by not smoking, no family history, good HDL, and no diabetes or hypertension.
